(54) Surface position detecting method and apparatus and scanning exposure method and apparatus

(57) Disclosed is a surface position detecting method wherein an object (4) with a region having a pattern structure formed thereon is relatively and scanningly moved relative to surface position detecting means (10-19,26) and wherein surface positions of plural detection points within the region are measured by the surface position detecting means, and wherein the method includes detecting an error at each detection point during detection of the surface position through the surface position detecting means, which error results from a difference in pattern structure between the detection points, and correcting, as the object is relatively and scanningly moved relative to the surface position detecting means so that the surface position of each detection point in the region is detected by the surface position detecting means, the result of detection at each detection point on the basis of the error corresponding to that detection point.

FIG. 1

EP 0 762 215 A1

Description

This invention relates to a surface position detecting method and apparatus and, more particularly, to a surface position detecting method and apparatus applicable to a slit-scan type or scanning exposure type exposure apparatus, for continuously detecting the position or tilt of the surface of a wafer with respect to the direction of an optical axis of a projection optical system. In other aspects, the invention is concerned with a scanning exposure method using such surface position detecting method and a method of manufacturing a semiconductor device using the exposure method.

Recently, the size of a memory chip is gradually increasing due to the need for enlargement in capacity of memory in contrast to the need for reduction in cell size and in resolvable line width of an exposure apparatus. For example, it has been reported that in the first generation of 256M the size is about 14x25 mm.

With this chip size, the exposure region of a diameter 31 mm of a reduction projection exposure apparatus (stepper) which is currently used as an exposure apparatus for a critical layer, allows exposure of only one chip per one exposure, such that the throughput is very low. It is therefore desired to develop an exposure apparatus of a large exposure area. As a large picture field exposure apparatus, conventionally, reflection projection exposure apparatuses have been used widely as a semiconductor exposure apparatus for rough layer or as an exposure apparatus for a large picture field liquid crystal display device such as a monitor, wherein a large throughput is required. These exposure apparatuses are slit-scan type (scanning exposure type) exposure apparatuses based on mask-wafer relative scan, wherein a mask is linearly scanned with an arcuate slit-like illumination light and, by using a concentric reflection mirror optical system, the whole surface of a wafer is exposed at once.

As regards the focusing of a mask image in these apparatuses, in order to successively bring the surface of a photosensitive substrate (wafer or glass plate coated with a photoresist or the like) into registration with a best imaging plane of a projection optical system, level measurement and corrective drive for auto-focusing and auto-leveling are continuously performed during the scanning exposure process.

Level and surface position detecting mechanism in such apparatus uses a method which uses an oblique projection optical system wherein light is projected to the surface of a wafer obliquely from above and wherein reflection light from the photosensitive substrate is detected as a positional deviation upon a sensor, or a method which uses a gap sensor such as an air micro-sensor or electrostatic capacity sensor. From measured values of level during the scan, corrective drive amount to the level (height) and tilt as the measurement position passes the exposure slit region is calculated, and correction is made.

If a projection optical system of a currently uses slit-scan type exposure apparatus is modified so as to provide a resolving power that meets 256M or larger, the following problems will arise.

That is, with increasing numerical aperture (N.A.) of a reduction projection system to meet further miniaturization of a circuit pattern, the tolerance for depth of focus in the pattern transfer process is reduced more and more. In exposure apparatuses currently used for a rough process, tolerable depth is not less than 5 microns. Thus, a measurement error included in a measured value, being measured successively during the scanning exposure, or the effect of a surface step within a chip can be disregarded. However, taking into account the applicability to 256M, the tolerable depth will be not less than 1 micron. Therefore, it is necessary to correct the aforementioned measurement error or the effect of a surface step within a chip (pattern structure within a chip).

In reduction projection exposure apparatuses, plural chips having the same pattern structure are formed on a photosensitive substrate, and the surface shape thereof is substantially reproduced at the exposure position. Thus, by executing trial printing using a pilot wafer prior to the lot processing, it is possible to correct the offset described above. Namely, it is possible to perform calibration to measurement points of a focus detection system. However, in a slit scan type exposure apparatus wherein plural points within an exposure region are measured while executing the scan, if calibration of the focus sensor is to be performed with respect to each measurement point and by printing, and if correction is to be done to twenty (20) points within a chip, in order to check the image quality through a microscope, it takes a long time, twenty times longer than that made in the reduction projection exposure apparatus. This considerably lowers the production efficiency.

Also, even if the sensor is arranged to observe the resist surface stably, making correction along the surface will undesirably cause defocus in the following case. That is, the structure of a memory within the exposure region comprises a memory cell portion and peripheral circuit portions. Usually, the exposure region in which critical resolution performance is required is concentrated to the memory cell portion.

In an example of a 256M chip, it comprises a memory cell region wherein critical line width transfer is required and peripheral circuit portions of loose rule, extending longitudinally and laterally so as to divide the memory cell portion. Although flattening is done to the cell portion and peripheral circuit portion by using a CMP (chemical mechanical polishing) process or a recess array forming process, for example, there still remains a surface step of about 1 micron.

If correction in Z direction is going to be done exactly in accordance with a measured value while scanning this region such as shown in Figure 4A, namely, if the exposure image plane of the slit is going to be tracked

continuously along the surface of the resist, and if the width of the slit in the scan direction (i.e., size of minor side) is 5 mm whereas the peripheral circuit portion has a width 2 mm, then there occurs defocus of about 1 micron in the regions (hatched regions in Figure 4A) of size 2 mm of the memory cell which regions are at opposite sides of the peripheral circuit portion having the surface step. Since the line width control for peripheral circuit portion is loose as compared with that for the memory cell, the focus depth enlarges accordingly.

Considering the points described above, it is not desirable to cause the exposure image plane to follow the real surface step (pattern structure). From the viewpoint of precision, it will be advantageous to control the surface step data as correction amount. Any way, there is no offset control and correction procedure established.

It is an object of one aspect of the present invention to provide a surface position detecting method and apparatus by which calibration of a focus measuring system can be performed with respect to a number of points and by which the position of the surface of a wafer can be detected with good precision.

It is an object of one particular aspect of the present invention to provide a high-precision surface position detecting method and apparatus for a slit-scan type exposure process.

In accordance with an aspect of the present invention, there is provided a surface position detecting method wherein an object with a region having a pattern structure formed thereon is relatively and scanningly moved relative to surface position detecting means and wherein surface positions of plural detection points within the region are measured by the surface position detecting means, said method comprising the steps of: detecting an error at each detection point during detection of the surface position through the surface position detecting means, which error results from a difference in pattern structure between the detection points; and correcting, as the object is relatively and scanningly moved relative to the surface position detecting means so that the surface position of each detection point in the region is detected by the surface position detecting means, the result of detection at each detection point on the basis of an error corresponding to that detection point.

In one preferred form of this aspect of the present invention, the object has plural regions each having the same pattern structure as that of the first-mentioned region, and said method further comprises correcting, as the object is relatively and scanningly moved relative to the surface position detecting means so that the surface positions at locations within the regions corresponding to the detection points are detected by the surface position detecting means, the result of detection at each detection point on the basis of an error corresponding to that detection point.

Said error detecting step may comprise detecting a surface shape of the object on the basis of surface position data related to corresponding locations in the re-

gions, and detecting the error on the basis of the surface shape.

In accordance with another aspect of the present invention, there is provided a scanning exposure method wherein a reticle and a wafer are scanningly moved in a timed relation relative to a projection optical system and wherein, for projection of a pattern of the reticle onto the wafer through the projection optical system, surface positions at plural detection points, arrayed along a scan direction, within an exposure region on the wafer having the same pattern structure are sequentially detected so that the exposure region is placed at an image plane position of the projection optical system, said method comprising the steps of: detecting an error at each detection point during detection of the surface position which error results from a difference in pattern structure between the detection points; and correcting, as the surface positions at the detection points are detected sequentially, the result of detection at each detection point on the basis of an error corresponding to that detection point.

In one preferred form of this aspect of the present invention, the wafer has plural regions each having the same pattern structure as that of the first-mentioned region, and said method further comprises correcting, as the surface positions at locations within the regions corresponding to the detection points are detected sequentially, the result of detection at each detection point on the basis of an error corresponding to that detection point.

Said error detecting step may comprise detecting a surface shape of the wafer on the basis of surface position data related to corresponding locations in the regions, and detecting the error on the basis of the surface shape.

In accordance with a further aspect of the present invention, there is provided a method of detecting a surface shape of an object having regions with the same pattern structure, wherein surface positions at corresponding locations in the regions of the object are detected by using surface position detecting means arranged to detect a surface position with light projected obliquely to the object, said method comprising: a first detecting step for detecting surface positions at corresponding locations within the regions by using the surface position detecting means; a driving step for moving the object to a predetermined position on the basis of the detection at said first detecting step; a second detecting step for detecting again, after said driving step, the surface positions at the corresponding locations in the regions by using the surface position detecting means; and a calculating step for calculating the surface positions of the regions on the basis of a driving amount at said driving step and of the detection at said second detecting step.

Embodiments of the present invention will now be described with reference to the accompanying drawings, in which:

Figure 1 is a fragmentary and schematic view of a slit-scan type projection exposure apparatus according to one embodiment of the present invention for carrying out a surface position detecting method of one aspect of the present invention.

Figure 2 is a schematic view for explaining positional relation between exposure slit and measurement points, in the surface position detection by a detection optical system.

Figure 3 is a plan view for explaining an example of arrayed exposure regions on a wafer and selection of sample shots to which pre-scanning is to be done.

Figures 4A and 4B are schematic views for explaining the relation between an image plane position of slit exposure with focus control and an exposure region representing IC surface topography during scan.

Figure 5 is a flow chart for explaining, as an example, main operations in offset measurement and surface position correction during exposure of shots, in accordance with a surface position detecting method of one aspect of the present invention.

Figure 6 is a flow chart for explaining, as an example, lot processing that uses a surface position detecting method of one aspect of the present invention.

Figure 7 is a flow chart for explaining, as an example, offset measurement and surface position corrective motion during exposure of shots.

Figure 8 is a schematic view for explaining the necessity of corrective motion for calculation of precision focus offset.

Figure 9 is a schematic view for explaining details of offset calculation.

Figures 10A - 10D are schematic views for explaining positional relationship between the slit and the surface position sensor means during slit scan exposure.

Figure 1 is a fragmentary and schematic view of a slit-scan type projection exposure apparatus according to one embodiment of the present invention for carrying out the surface position detecting method of one aspect of the present invention.

Denoted in Figure 1 at 1 is a reduction projection lens having an optical axis AX and an image plane which is perpendicular to Z direction as illustrated. Reticle 2 is held by a reticle stage 3, and a pattern of the reticle 2 is projected by the reduction projection lens in reduced scale of 1:4 or 1:2 corresponding to the magnification thereof, whereby an image is formed on the image plane. Denoted at 4 is a wafer having a surface coated with a resist. Through preceding exposure process or processes, a number of exposure regions (shots) having the same pattern structure are formed on the wafer. Denoted at 5 is a stage on which the wafer is placed. The wafer stage 5 comprises a chuck for attracting and fixing the wafer 4 to the stage 5, an X-Y stage movable horizontally along X-axis direction and Y-axis direction, a leveling stage movable along Z-axis direction (optical axis AX direction of the projection lens 1) and also rotationally movable about X and Y axes, and a rotatable

stage being rotationally movable about the Z axis. The wafer stage 5 thus provides a six-axis correction system for bringing the image of the reticle pattern into coincidence with the exposure region on the wafer.

Denoted at 10 - 19 in Figure 1 are components of a detection optical system for detecting surface position and tilt of the wafer 4. Among them, denoted at 10 is a light source which comprises a white light source or an illumination unit arranged to project light of high-luminance light emission diode having different peak wavelengths. Denoted at 11 is a collimator lens for transforming the light from the light source 10 into parallel light having substantially uniform sectional intensity distribution. Denoted at 12 is a slit member of prism-like shape, comprising a pair of prisms being cemented so that their slant surfaces are opposed to each other. A plurality of openings (e.g., six pinholes) are formed at the cemented surface by using a light blocking film such as chromium film. Denoted at 13 is an optical system comprising a bi-telecentric optical system, which serves to direct six independent light beams from the pinholes of the slit member 12 to six measurement points on the wafer 4 surface, by way of a mirror 14. While only two light beams are illustrated in Figure 1, each beam in the drawing represents three light beams which are placed in the direction perpendicular to the sheet of the drawing. Here, with respect to the lens system 131, the plane on which the pinholes are formed and the plane which includes the surface of the wafer 4 are disposed to satisfy the Scheimpflug's condition.

In this embodiment, the incidence angle ϕ of each light beam from the light projecting means upon the wafer 4 surface (i.e., the angle defined with respect to a normal to the wafer surface, that is, with respect to the optical axis) is not less than 70 deg. As shown in Figure 3, there are a plurality of exposure regions (shots) having the same pattern structure, on the wafer 4 surface. The six light beams passing the lens system 13 are projected and imaged upon separate measurement points on the pattern region, as shown in Figure 2. Also, in order that the six measurement points are observed independently of each other within the plane of the wafer 4 surface, light is projected in a direction rotated from the X direction (scan direction 5a) along the X-Y plane by an angle θ (e.g., 22.5 deg.).

In this manner and as disclosed in Japanese Patent Application No. 157822/1991, spatial disposition of the respective components is set appropriately to facilitate high precision detection of surface position information.

Next, the structure at a side for detecting reflection light from the wafer 4, namely, the structure of elements 15 - 19, will now be explained.

Denoted at 16 is a light receiving optical system which comprises a bi-telecentric optical system. It receives six reflection light beams from the wafer 4 surface, by way of a mirror 15. Stop member 17 is provided within the light receiving optical system 16, in common to the six measurement points. It serves to interrupt

higher order diffraction light (noise light) produced by a circuit pattern formed on the wafer 4. The light beams passed through the bi-telecentric light receiving optical system 16 have their axes parallel to each other, and they are re-imaged upon a detection surface of a photoelectrically converting means unit 19 into light spots of the same size, by means of six separate correction lenses of a correction optical system unit 18.

As regards the light receiving side (elements 16 - 18), plate tilt correction is made so that the measurement points on the wafer 4 surface and the detection surface of the photoelectrically converting means unit 19 are placed in an optically conjugate relation. Therefore, any local inclination at any measurement point does not cause a change in position of the pinhole image on the detection surface. Thus, in response to a change in level (height) of each measurement point in the optical axis AX direction, the pinhole image on the detection surface changes.

The photoelectrically converting means unit 19 comprises six one-dimensional CCD line sensors. This is advantageous as compared with the structure using a two-dimensional sensor, in the following points. First, in structuring the correction optical system unit 18, separation of the photoelectrically converting means unit expands the tolerance for disposition of optical components or mechanical holders. Second, while the optical magnification of the portion from the mirror 15 to the correction optical system unit 18 should be made large in order to improve the detection resolution, the arrangement wherein light path is divided and divided lights are incident on separate sensors enables to make the structure compact. Further, in the slit scan type it is required to perform focus continuous measurement during the exposure process so that reduction of measurement time is much desired. When a two-dimensional CCD sensor is used, while it may be attributable to reading of data more than needed, it takes a long read-out time 10 times longer or more than that when one-dimensional CCD sensors are used.

Next, the exposure system of slit scan type will be explained.

As shown in Figure 1, the reticle 2 is attracted to and held by the reticle stage 3. Then, it is scanned along a plane perpendicular to the optical axis AX of the projection lens 1 and in the direction of an arrow 3a (X-axis direction), at a constant speed. Additionally, as regards a direction perpendicular to the arrow 3a (i.e., Y-axis direction, perpendicular to the sheet of the drawing), correction drive is made so that it is scanned while holding its target coordinate position constantly. Positional information of the reticle stage with respect to the X and Y directions, is measured continuously by projecting laser beams from a reticle X-Y interferometer system 21 to an X-Y bar mirror 20 fixedly mounted on the reticle stage of Figure 1.

Exposure illumination optical system 6 comprises a light source such as an excimer laser, for example, for

producing pulsed light. It further comprises a beam shaping optical system, an optical integrator, a collimator and a mirror, for example, all being unshown in the drawing. The components of the exposure illumination optical system are made of a material or materials efficiently transmit or reflect pulse light which is in deep ultraviolet region. The beam shaping optical system serves to transform the sectional shape (including size) of a received beam into a desired shape. The optical integrator serves to uniform the light distribution characteristic so as to illuminate the reticle 2 with uniform illuminance. By means of a masking blade (not shown) within the exposure illumination system 6, a rectangular illumination region corresponding to the chip size is defined. The pattern of the reticle 2 as illuminated partly by that illumination region, is projected onto the resist coated wafer 4 thorough the projection lens 1.

Main control unit 27 shown in Figure 1 serves to control the whole system, such that, while adjusting the position of the slit image of the reticle 2 with respect to a predetermined exposure region of the wafer 4 along the X-Y plane (i.e., X and Y positions and rotation θ about Z axis) as well as the position in the Z direction (i.e., rotations α and β about X and Y axes, respectively, and height Z along Z axis), the reticle and the wafer are scanned in a timed relation relative to the projection optical system, and also that the pattern of the reticle 2 is projected and printed by scan onto the wafer. Namely, as regards alignment of the pattern of the reticle in X-Y plane, control data is calculated from positional data produced the reticle interferometer 21 and a wafer stage interferometer 24 as well as from positional data produced by an alignment microscope (not shown), by which control data the reticle position controlling system 22 and the wafer position controlling system 25 are controlled.

When the reticle stage 3 is scanned or scanningly moved in the direction of arrow 3a in Figure 1, the wafer stage 5 is scanningly moved in the direction of an arrow 5a at a speed corrected by an amount corresponding to the reduction magnification of the projection lens. The scan speed of the reticle stage 3 is determined on the basis of the width, in the scan direction, of the masking blade (not shown) of the exposure illumination optical system 6 and of the sensitivity of the resist applied to the wafer 4, so as to assure higher throughput.

As regards alignment of the reticle pattern in the Z-axis direction, that is, registration of the same with the image plane, the leveling stage of the wafer stage is controlled through the wafer position controlling system 25, on the basis of the result of calculation of the surface position detecting system 26 that detects height data of the wafer 4. Namely, from height data related to three light spots (for wafer level measurement) defined to the scan direction and adjacent to the slit, tilt in a direction perpendicular to the scan direction as well as the height with respect to the optical axis AX direction are calculated. Then, the amount of correction into coincidence

with the best image plane position at the exposure position is determined, on the basis of which correction is made.

Now, the process of detecting the position of an exposure region of the wafer 4 in accordance with the surface position detecting method of one aspect of the present invention, will be explained.

In order to detect the position of the exposure region on the wafer 4 in the Z direction, that is, to detect a deviation of tilt (α and β) and position (Z) with respect to the image plane, it is necessary to measure the surface of the wafer 4 accurately and to take into account the relation between the shape of illumination region and the pattern structure (actual surface step) of the exposure region. When an optical detection system is used for the former (accurate surface measurement), there are factors of detection error such as follows. That is, there is an effect of interference between light reflected by the resist surface of the wafer 4 and light reflected by the substrate surface of the wafer 4. Such effect changes in dependence upon the material of the substrate surface which is, in a broad meaning, a pattern structure. For high reflection wiring material such as Al, for example, it is of an amount not negligible. When an electrostatic capacity sensor is used as a wafer surface position detecting sensor, in a case of GaAs wafer which is used as a substrate of a high-speed element or light emitting diode, because of dielectric material, it has a large measurement offset as compared with a Si wafer. While the point of pattern structure (actual surface step) of the exposure region has been mentioned as another example of measurement error, it is not desirable to cause the exposure image plane to follow the actual surface step, as has been described before. From the viewpoint of precision, the surface step data should preferably be used as a correction amount, such as shown in Figure 4B.

This correction method will be explained with reference to the flow chart of Figure 5.

At step 101, a start command is inputted. At step 102, a wafer is loaded onto the stage, and it is held attracted to the chuck. Then, for measurement of the surface shape (plural surface positions) of an exposure region of a chip, at step 103 and as shown in Figure 3, pre-scan measurement is performed to plural sample shots as depicted by hatching (i.e., surface positions at plural locations in respective exposure regions are measured while actually scanning the wafer). That is, at plural points on the wafer, the surface state (focus measurement data at multiple points) is measured through scan. Thereafter, by using the measured values of surface position (surface position data), at step 104, a correction amount (error attributable to the pattern structure) for correcting the surface position detected values during the scan exposure into the distance to the best exposure image plane position, is calculated. That is, from the scan measurement data, a measurement error and a surface step correction amount are calculated in

terms of a difference with the best focus position.

When this is completed, at step 105 and during the scan exposure, the surface position detected value at each detection point (where surface position detection is performed) is corrected in accordance with the correction amount corresponding to the pattern structure at that detection point. On the basis of the thus corrected surface position detected value, the exposure region is brought into coincidence with the exposure image plane, and the exposure process is performed. That is, the focus measurement data is corrected by using the correction amount, and a correction amount to the image plane position is calculated. Based on this, the exposure region is brought into coincidence with the image plane.

The correction amount determined through this pre-scan measurement depends on the pattern structure (actual surface step in the exposure region or material of the substrate). For wafers of the same lot or those having been treated by the same process, it is considered that they have the same pattern structure. Thus, the correction amount determined with respect to the first one of those wafers may be used for the remaining wafers. The flow chart of Figure 6 shows this.

In the flow chart of Figure 6, at step 204, pre-scan is done. That is, at plural points on the wafer, the surface state (focus measured data at multiple points) in the exposure regions is measured by scan. At step 205, surface detection focus data correction amount is calculated. That is, from the scan measurement data, a measurement error and surface step correction amount are calculated in terms of the difference with the best focus position. Step 206 is a memorizing step where the measurement error, the surface step correction amount and positional information of the measurement points are stored into the main control unit 27. At step 207, scan exposure is performed. That is, the focus measured data is corrected by using the correction amount, and correction amount to the image plane position is calculated. The exposure regions is then brought to the image plane.

At step 210, statistical processing (such as averaging of plural datums of a number "i", for example) is performed to the data memorized at step 203.

At step 213, scan exposure is performed. That is, the focus measured data is corrected by using the measurement error, surface step correction amount and positional information of the measurement points, obtained at step 210. Correction amount to the image plane position is calculated, and the exposure region is brought to the image plane.

With the sequence such as illustrated in the flow chart of Figure 6, the throughput can be improved significantly.

Now, description will be made on a process of measuring an offset (correction amount) for correcting measurement error factors, depending on the pattern structure (such as actual surface step in exposure re-

gion or material of the substrate), from the detected values of surface position obtained during the scan exposure.

Referring to the flow chart of Figure 7, the manner of determining offset value for correcting an error depending on the pattern structure (actual surface step in exposure region or material of the substrate) which is a problem in detection of surface position and tilt of the surface of a wafer, on the basis of the surface position measured data, will be explained.

First, for offset calculation, plural exposure regions to be scan measured are determined beforehand as sample shots. As regard these sample shots, it is desirable to select the positions of those exposure regions such as depicted by hatching in Figure 3, for example, which are symmetrical with each other with respect to the center of the wafer so that they are less affected by the surface precision of the wafer and from which regions the information related to the whole surface is easily obtainable. This is because, while taking into account the polishing treatment such as CMP or any other treatment, due to the shape characteristic of the wafer which is of circular shape, deformation will occur symmetrically with respect to the center.

First, at step 1, a wafer 4 is place on the chuck of the wafer stage 5, and it is attracted to and held by the chuck. Then, at step 2, an alignment mark of a particular shot is moved to a position below an autoalignment microscope (not shown) and, after focus correction of the autoalignment microscope, the position of the alignment mark is measured. This measurement is performed to shots of a number "g". From alignment data produced as a result of the measurement, the shot layout data at all exposure positions upon the wafer is corrected, such that during the scan exposure every exposure region can be aligned correctly with the reticle. Namely, the correction amount for correcting deviation of each exposure position with respect to the reference position of the reticle pattern is calculated. If this is done, since the patterns of respective exposure positions have been processed by the same reticle, the pattern structure at the time of the j-th surface position measurement operation as defined in terms of the stage coordinates, at respective exposure positions, will be completely the same within the range of alignment precision. Actually, it has been confirmed that, at the measurements, substantially the same measured data are produced. In accordance with the layout information obtained at this step, subsequent sample shot movement and scan of sample shot are performed. Thus, during the scanning measurement to different shots, measurement is made to the same location of the same pattern structure within the range of the alignment precision. At the stage of this measurement, a tilt component of the whole wafer surface is measured by means of the focus detecting system and, prior to step 3, the leveling stage within the wafer stage 5 is actuated to correct the tilt component of the whole wafer.

When the shot layout correction at step 2 is completed, then the sequence goes at step 3 to offset measurement procedure. First, in accordance with an output signal of the wafer laser interferometer system 24, the wafer is moved to the position of a j-th measurement point (detection point) among the predetermined sample shots S_i ($i = 1$ to m) (step 3 and step 4). There, the detection optical system (10-19) is used to detect surface position measured data of the wafer surface at the j-th measurement point in the exposure region, that is, the position Z_{jk} ($k = 1$ to p) of the wafer surface in the optical axis AX direction. Here, since during actual exposure process it is measured in the vicinity of the image plane of the projection lens, it is necessary that in the offset measurement the position is measured in the vicinity of the image plane. If the wafer surface shape is not deformed, in order to detect the surface shape of the whole wafer surface, the level of the wafer may be held fixed (by holding the height of the leveling state fixed) and surface measurement may be repeated while moving the wafer stage stepwise in X and Y directions. However, with repetition of wafer treatments, the shape of the whole wafer surface will be deformed into a concaved shape or convexed shape such as illustrated in Figure 8. If an oblique light projection type detection optical system is used to such a generally deformed wafer, executing the focus measurement while holding the wafer level fixed as shown in Figure 8(a) will cause lateral shift of the incidence position of the detection light beam with a change in shape of the wafer or a change in surface level of the wafer. This results in misreading of the position, different from the pattern which is inherently to be observed in the vicinity of the exposure image plane. In consideration of this, as shown in Figure 8(b), at respective measurement positions, the position of the Z stage is corrected and shifted toward the image plane. Referring back to Figure 7, this operation will be explained.

First, at step 5, a leveling stage position detecting system (not shown) is used to detect the position of the leveling stage as the same is held at the same position as the exposure position within the X-Y plane. The position (Z_0, α_0, β_0) of the leveling stage of the wafer stage 5 is memorized (measurement is done only with respect to the first point of a first sample shot, and the resultant data is used in correction calculation for the remaining points). Thereafter, surface position measured data at the wafer surface is detected. By using that value, the wafer surface is moved to the image plane position, and Z correction drive is performed. By executing Z correction drive of the wafer surface to the image plane position, the problem of lateral shift of the detection light beam is solved (Figure 8(b)). From the corrected position of the leveling stage (Z_j, α_0, β_0) and the surface position measured data at that position, namely, from the data of the position Z_{0jk} ($k = 1$ to p) of the wafer surface in the optical axis AX direction,

$$Z_{jk} \ (k=1 \text{ to } p) = Z_{0jk} + Z_j - Z_0$$

is calculated. The described is an example wherein the correction amount ($Z_j - Z_0$) is based on the result of detection of the position of the leveling stage in the Z direction. Since, however, the correction drive of the leveling stage is based on the magnitude of the measured value Z_{0jk} , if the driving error of the leveling stage is negligible, a measured value Z_{0jk} before correction drive and a value Z_{0jk} after correction drive may be added. A signal corresponding to the position Z_{0jk} ($k = 1$ to p) is applied from the detecting means 19, comprising CCD linear sensors of a number "p" to a focus signal processing device 26. After correction calculation as described, it is memorized as a measured value at the j-th measurement point. Also, at step 6, the position (X,Y) of the wafer stage at that position is memorized.

At step 7, discrimination is made as to whether similar measurement has been done to all the measurement points ($j = 1$ to n), and, if not, the wafer is moved to the subsequent measurement point (step 4) and similar measurement is repeated. If all measurement points are completed, then at step 8 discrimination is made as to whether measurement to all the sample shots ($i = 1$ to m) is completed or not. If not, the sequence goes back to step 3.

If at step 8 completion of measurement to all the sample shots is confirmed, then at step 9 offset correction amount C_{jk} at every sensor position and every measurement point, at the measurement position in the exposure region, is calculated. In relation to this calculation, Japanese Patent Publication, Publication No. 52707/1990 discloses a surface position detecting method for a stepper, wherein measurement is made to a single point in exposure region. In the present invention, taking into account the applicability to a scanning exposure apparatus, the following modification is made so that it can be used for measurement offset correction at plural points in exposure region. That is, on the basis of measured value Z_{jk} of measurement sensors k at measurement points j within the exposure position as obtainable with the present offset measurement sequence, surface shape functions $F_{np}(x,y)$ (the number of data points of each surface shape function corresponds to m points of sample shot S_i ($i = 1$ to m)) that represents the wafer surface shapes of a number "nxp", are determined. The order of curved surface or expansion equation of these surface shape functions $F_{np}(x,y)$ are determined beforehand in terms of predetermined polynomial. For determining offset amounts of respective surfaces, the measured value Z_{jk} is used as surface position data and, by using least square method, the coefficient of F_{np} , that is, the offset correction amount, is determined.

More specifically, a constant term C_{jk} that satisfies the following relation is determined:

$$\iint (F_{jk}(x,y) - Z_{jk}(x,y)) 2cdxdy = 0 \ (j=1 \text{ to } n, k=1 \text{ to } p)$$

The sequence of correction value calculation will be explained with reference to Figure 9A and in connection with an example wherein the number m of sample shots is $m = 3$, the number j of measurement points is $j = 3$ and the number k of measurement sensors is $k = 3$. For convenience in explanation, it is assumed that the flatness of the wafer is one dimensional and, in terms of equation of plane $aX+bY+cZ = d$, it is assumed that $b = c = 0$.

The sectional structure of the wafer is such as shown in Figure 9A wherein, at a measurement point $j = 1$, measuring sensors $k = 1, 2$ measure the same level and only a sensor $k = 3$ measures a surface step (for example, at portions $k = 1, 2$ of a memory cell region where underlying materials are different, due to the effect of interference, the measured value shifts to the substrate side), and this structure is repeated at $j=3$. At the measurement point $j = 2$, only by $k = 2$, a large measurement value is produced (for example, a peripheral circuit region as compared with a memory cell). Since the pattern in this exposure region is consistent within the range of alignment precision, when the sample shots of $m = 1$ to 3 are measured, the surface position measured value Z_{jk} is reproduced.

From measured values Z_{jk} of a number twenty-seven produced in this manner, offset C_{jk} is determined by the following calculation. That is, by using data Z_{21} in Figure 9A as a reference (offset C_{21} at this position with respect to the image plane of the projection lens can be determined by actual exposure using a preceding wafer, for example), other C_{jk} is detected. Now, the surface F_{21} as formed by measured data Z_{21} of $m = 1$ to 3 is taken as a reference, that is, a constant term 0. In order to determine offset C_{22} of Z_{22} corresponding to a peripheral circuit region, as shown in Figure 9B, a difference related to the shape of the wafer between the surface shape functions F_{22} and F_{21} as determined by the measured values at Z_{22} of $m = 1$ to 3, may be detected.

Here, the difference corresponds to difference of d (segment) called in equation of plane, and its value can be calculated as C_{22} in the drawing. Similarly, with regard to C_{11} of Z_{11} being shifted due to the effect of interference, it may be detected as a difference of segment between F_{21} and F_{11} . Similar calculation is made for detection of other C_{jk} , and the results are stored into a memory.

Referring to Figures 7 and 10, the procedure of focus position measurement at each exposure position, the measured value correction based on D_{jk} , and correction of leveling stage position, will be explained.

At steps 11 and 12, the wafer stage 5 is moved to the position where the first measurement point of the N-th shot ($N = 1$ to w) is reached, that is, the position where during the exposure the focus measuring beam comes to the first measurement point of the N-th shot is

reached. This will be explained in detail. At step 12, Zjk measured value at the first measurement point of the N-th shot, more specifically, detection signals from three CCD linear sensors of the photoelectrically converting means unit 19 responsive to measurement beams to CR1, CR2 and CR3 in Figure 10A, is processed by the focus signal processing device 26, and height data Z11, Z12 and Z13 are produced. These height data involve offset errors due to a surface step or a measurement error due to interference. In consideration thereof, correction data of Cjk obtained at step 9 is used to detect a difference in the following manner to determine correct surface position measured data ZTjk of the wafer.

$$ZTjk = Zjk - Cjk$$

The value Cjk calculated here involves only a component of wafer deformation within exposure area where measurement offset attributable to the resist surface is corrected. Thus, on the basis of this surface position data, a least square plane is calculated (step 14).

Subsequently, at step 15, the wafer stage 5 is moved in the optical axis direction and in the tilt direction so as to correct the difference between the position of the leveling stage at the time of Zjk measurement and the current position thereof and to correct the difference between the exposure image plane of the projection lens 1 and the least square plane. By this, the exposure area of the wafer is brought into coincidence with the image plane of the projection lens. When correction drive for the j-th measurement points is completed, at step 16 discrimination is made as to whether all the measurement points are completed. Measurement and correction drive is repeated until $j = n$ is satisfied.

More specifically, in the state of Figure 10B, correction is made using data $j = 1$ and, simultaneously, focus measurement and offset correction are performed at the point $j = 2$. By using this correction data, at the stage where the position of Figure 10C is going to be scanned, correction is made using data $j = 2$ and, simultaneously, focus measurement and offset correction are performed at the point $j = 3$. By using this correction data, at the stage where the position of Figure 10D are going to be scanned, correction is made using data $j = 3$. When measurement and correction is completed up to point $j = n$, at step 17 discrimination is made as to whether all the shots of the wafer are completed or not. Scan exposure of shots is repeated until $N = w$ is satisfied.

The procedure of determining offset value, as a correction amount and from the measured data, for measurement error or surface step which raises a problem in detection of surface position or tilt of the wafer, that is, the procedure of calibration for sensors of multiple point focus detecting mechanism, should be done with respect to each of different processes wherein different patterns are formed. However, it is sufficient to perform measurement only to one wafer in one lot. For the re-

maining wafers in the same lot, offset Cij obtained with reference to the first wafer and store in a memory may be used in the focus measurement and correction. This enables high precision leveling correction and exposure without decreasing the throughput.

In the embodiment described above, an example wherein offset depending on the pattern of the wafer is corrected. However, the invention is not limited to this. For example, conventionally for calibration of an origin in multiple point focusing, a high precision flat surface is prepared or, alternatively, actual exposure is executed. In contrast, by performing the above-described procedure to a wafer having no pattern formed, offset for focus sensor mounting positions can be determined easily. Also, the invention is not limited to "surface". When a detection sensor for detecting level of a single point is used to perform scan focusing, similar offset correction procedure may be carried out to hold the surface of a memory cell at the image plane position, for example.

In the embodiment described above, one point in an exposure region such as a point in memory cell, where focus depth is most strict, is selected and exposed beforehand to thereby determine the best focus. However, the invention is not limited to "single point". Further, in a case where it is desired to perform measurement at one point to detect a change in environment of a lens, for example, to change the focus correction position separately within the exposure region, that is, in a case of a logic device, for example, whose surface height changes with location, the data Cij of surface position data offset may be corrected on the basis of a design value. More particularly, while taking into account the width of illumination region slit and from a two-dimensional map as defined by Cij, if the region with respect to which the offset should be changed is wider, Cij may be corrected by a value corresponding to the surface step.

The present invention is also concerned with a method of manufacturing a semiconductor device which utilizes the exposure process. In the method of manufacture a resist layer on the wafer is exposed to radiation and the exposed resist is then etched to form the semiconductor pattern. The exposure and etching steps can be repeated for further resist layers and the semiconductor wafer is subsequently cut into segments comprising the devices.

While the invention has been described with reference to the structures disclosed herein, it is not confined to the details set forth and this application is intended to cover such modifications or changes as may come within the purposes of the improvements or the scope of the following claims.

Claims

1. A surface position detecting method wherein an ob-

ject with a region having a pattern structure formed thereon is relatively and scanningly moved relative to surface position detecting means and wherein surface positions of plural detection points within the region are measured by the surface position detecting means, said method comprising the steps of:

detecting an error at each detection point during detection of the surface position through the surface position detecting means, which error results from a difference in pattern structure between the detection points; and
correcting, as the object is relatively and scanningly moved relative to the surface position detecting means so that the surface position of each detection point in the region is detected by the surface position detecting means, the result of detection at each detection point on the basis of an error corresponding to that detection point.

2. A method according to Claim 1, wherein the object has plural regions each having the same pattern structure as that of the first-mentioned region, and wherein said method further comprises correcting, as the object is relatively and scanningly moved relative to the surface position detecting means so that the surface positions at locations within the regions corresponding to the detection points are detected by the surface position detecting means, the result of detection at each detection point on the basis of an error corresponding to that detection point.

3. A method according to Claim 2, wherein said error detecting step comprises detecting a surface shape of the object on the basis of surface position data related to corresponding locations in the regions, and detecting the error on the basis of the surface shape.

4. A scanning exposure method wherein a reticle and a wafer are scanningly moved in a timed relation relative to a projection optical system for projection of a pattern of the reticle onto the wafer through the projection optical system, and wherein surface positions at plural detection points, arrayed along a scan direction, within an exposure region on the wafer having the same pattern structure are sequentially detected so that the exposure region is placed at an image plane position of the projection optical system, said method comprising the steps of:

detecting an error at each detection point during detection of the surface position which error results from a difference in pattern structure between the detection points; and
correcting, as the surface positions at the de-

tection points are detected sequentially, the result of detection at each detection point on the basis of an error corresponding to that detection point.

5. A method according to Claim 4, wherein the wafer has plural regions each having the same pattern structure as that of the first-mentioned region, and wherein said method further comprises correcting, as the surface positions at locations within the regions corresponding to the detection points are detected sequentially, the result of detection at each detection point on the basis of an error corresponding to that detection point.

6. A method according to Claim 5, wherein said error detecting step comprises detecting a surface shape of the wafer on the basis of surface position data related to corresponding locations in the regions, and detecting the error on the basis of the surface shape.

7. A method of detecting a surface shape of an object having regions with the same pattern structure, wherein surface positions at corresponding locations in the regions of the object are detected by using surface position detecting means arranged to detect a surface position with light projected obliquely to the object, said method comprising:

a first detecting step for detecting surface positions at corresponding locations within the regions by using the surface position detecting means;

a driving step for moving the object to a predetermined position on the basis of the detection at said first detecting step;

a second detecting step for detecting again, after said driving step, the surface positions at the corresponding locations in the regions by using the surface position detecting means; and

a calculating step for calculating the surface positions of the regions on the basis of a driving amount at said driving step and of the detection at said second detecting step.

8. A method of manufacturing a semiconductor device comprising the scanning exposure method of any one of claims 4 to 6 and fabricating a semiconductor device from the exposed wafer.

9. A surface position detecting apparatus comprising:

surface position detecting means for detecting surface positions of plural detection points on an object,

scanning means for scanning an object with a region having a pattern structure formed there-

eon relative to said surface position detecting
 means,
 detection means for detecting an error at each
 detection point during detection of the surface
 position by the surface position detecting means, which error results from a difference in
 pattern structure between the detection points;
 and
 correction means for correcting, as the object
 is relatively and scanningly moved relative to
 the surface position detecting means so that
 the surface position of each detecting point in
 the region is detected by the surface position
 detecting means, the result of detection at each
 detection point on the basis of an error corre-
 sponding to that detection point.

basis of the detection of the surface positions
 by the detection means after the movement of
 the object.

10. Scanning exposure apparatus comprising a projec-
 tion optical system for projecting a pattern of a ret-
 icle onto a wafer through the projection optical sys-
 tem, scanning means for relatively scanning the ret-
 icle and the wafer in a timed relation relative to the
 projection optical system, position detection means
 for sequentially detecting surface positions at plural
 detection points arrayed along a scan direction
 within an exposure region on the wafer having the
 same pattern structure so that the exposure region
 is placed at an image plane position of the projec-
 tion optical system, error detecting means for de-
 tecting an error at each detection position during de-
 tection of the surface position, which error results
 from a difference in pattern structure between the
 detection point, and correction means for correcting
 the result of detection at each detection point as the
 surface portions at the detection points are detected
 sequentially on the basis of an error corresponding
 to that detection point.

11. Apparatus for detecting a surface shape of an ob-
 ject having regions with the same pattern structure,
 comprising:

surface position detecting means arranged to
 detect a surface position by projecting light ob-
 liquely onto the object;
 detection means for detecting surface positions
 at corresponding locations within the regions
 using the surface position detecting means;
 means for moving the object to a predeter-
 mined position on the basis of the detection by
 the detection means, wherein the detection
 means is adapted to detect the surface posi-
 tions after the object has been moved to the
 predetermined position using the surface posi-
 tion detecting means; and
 calculation means for calculating the surface
 positions of the regions on the basis of the
 amount of movement of the object and on the
